TECHNISCHE UNIVERSITÄT DARMSTADT

Sommersemester 2020

Aufgabe 1: Linear Regression

In this exercise, you will implement various kinds of linear regression using the data lin_reg_train.txt and lin_reg_test.txt. The files contain noisy observations from an unknown function $f : \mathbb{R} \mapsto \mathbb{R}$ In both files, the first column represents the inputs and the second column represents the outputs. You can load the data using numpy.loadtxt. For all subtasks, assume that the data is identically and independently distributed according to

$$y_i = \mathbf{\Phi}\left(\mathbf{x_i}\right)^\top \mathbf{w} + \epsilon_i,$$

where

$$\epsilon_i \sim \mathcal{N}\left(0, \sigma^2\right)$$

and $\Phi : \mathbb{R}^1 \to \mathbb{R}^n$ is a feature transformation such that

$$\mathbf{y} \sim \mathcal{N}\left(\mathbf{\Phi}(\mathbf{X})^\top \mathbf{w}, \sigma^2 \mathbf{I}\right)$$

Additionally, make sure that your implementations support multivariate inputs. The feature transformation are given in each task, if no basis functions are stated explicitely use the data as is $\Phi(x) = x$.

1a)

Implement linear ridge regression using linear features, i.e. the data itself. Include an additional input dimension to represent a bias term and use the ridge coefficient $\mu = 0.01$.

1. Explain: What is the ridge coefficient and why do we use it? (1)

ridge coefficient lambda in

$$\mathbf{w}_{\mathrm{MAP}} = \left(\Phi\Phi^{\mathrm{T}} + \frac{\alpha}{\beta}\mathbf{1}\right)^{-1} \Phi\mathbf{y}$$

reason: regularizes the pseudo-inverse as "learning rate"

2. Derive the optimal model parameters by minimizing the squared error loss function. (3)

```
import numpy as np
import matplotlib.pyplot as plt

# task a, b and c
def ridge_regression(data_train, data_test, coe_=0.01, n=1, plot=True):
    """
    ridge_regression use linear features
    :param data_train: [array], N*2 train data
    :param data_test: [array], N*2 test data
    :param coe_: [float], ridge coefficient
    :param n: [int], polynomials of degrees
    :param plot: [boolean], plot or not
    :return prediction: [array], N*1 prediction result of training data
    :return rmse_train: [float], root mean squared error of the train data
    :return rmse_test: [float], root mean squared error of the test data
    """
    def data_split(data, n=n):
        """
        split input data and target data,
        add bias in input data
        :param data: [array], N*2 input regression data
        :return X: [array], N*n input data with bias
        :return y: [array], N*1 target data
        """
        try:
            # input, target split
            X = data[:, 0].reshape(-1, 1)
            y = data[:, 1].reshape(-1, 1)

            # initial
            X_poly = np.ones(X.shape)
            # add a bias in input
            for i in range(1, n + 1):
                X_poly = np.hstack((X_poly, np.power(X, i)))
            return X_poly, y

        except IndexError:
            # prepare for plot
            X = data.reshape(-1, 1)

            # initial
            X_poly = np.ones(X.shape)
            # add a bias in input
            for i in range(1, n + 1):
                X_poly = np.hstack((X_poly, np.power(X, i)))
            return X_poly

    X_train, y_train = data_split(data_train)
    X_test, y_test = data_split(data_test)

    # calculate the weight matrix with training data set
    w = np.linalg.pinv(X_train.T @ X_train + coe_ * np.eye(X_train.shape[1])) @ X_train.T @
        y_train

    def loss(X, y, w, coe_=coe_):
```

```
        """
        loss function of ridge regression
        :param X: [array], N*n input data with bias
        :param w: [array], n*1 weight matrix
        :param coe_: output data
        :return phi: [float], loss function result
        :return rmse: [float], root mean squared error
        """
        phi = 1/2 * np.linalg.norm(X @ w - y) ** 2 + coe_/2 * np.linalg.norm(w) ** 2
        rmse = np.sqrt(np.linalg.norm(X @ w - y) ** 2 / len(y))
        return phi, rmse

    _, rmse_train = loss(X_train, y_train, w)
    _, rmse_test = loss(X_test, y_test, w)

    if plot:
        def plot_result(X, y, w):
            """
            plot prediction vs. target
            :param X: [array], N*n input data with bias
            :param y: [array], N*1 target data
            :param pre: [array], N*1 prediction data
            :return: None
            """
            # define independent variable
            x = np.linspace(X[:, 1].min(), X[:, 1].max(), 200)
            x = data_split(x)
            ax = plt.figure().gca()
            ax.plot(X[:, 1], y, 'ko', label='training data')
            ax.plot(x[:, 1], x @ w, 'b', label='predicted function')
            plt.title(f"prediction vs. target in training data, polynomials of degrees={n}")
            plt.legend()
            plt.show()

        plot_result(X_train, y_train, w)

    return rmse_train, rmse_test

data_train = load_data("lin_reg_train")
data_test = load_data("lin_reg_test")

# task a
rmse_train, rmse_test = ridge_regression(data_train, data_test)
print(f"root mean squared error of the training data: {rmse_train}")
print(f"root mean squared error of the test data: {rmse_test}")
```

3. Report the root mean squared error of the train and test data under your linear model with linear features. (2)

root mean squared error of the training data: 0.4121780156736108
root mean squared error of the test data: 0.384288169925978643

4. Include a single plot that shows the training data as black dots and the predicted function as a blue line. (2)

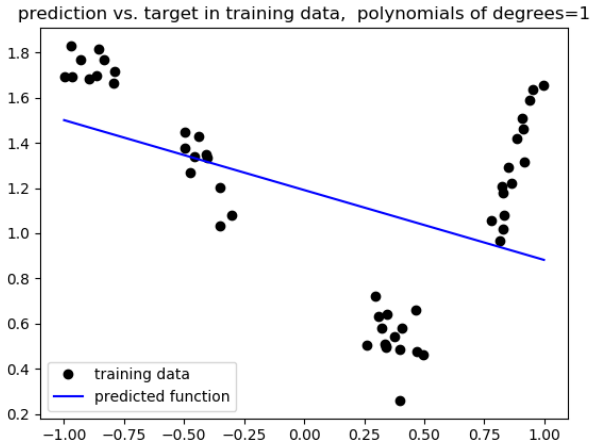

Abbildung 1: task 4

1b)

Implement linear ridge regression using linear features, i.e. the data itself. Include an additional input dimension to represent a bias term and use the ridge coefficient $\mu = 0.01$.

For polynomials of degrees 2, 3 and 4:
1. Report the root mean squared error of the training data and of the testing data under your model with polynomial features. (2)

polynomials of degrees=2, root mean squared error of the training data: 0.21201447265968615
polynomials of degrees=3, root mean squared error of the training data: 0.08706821295481745
polynomials of degrees=4, root mean squared error of the training data: 0.0870126130663817

polynomials of degrees=2, root mean squared error of the test data: 0.21687242714148716
polynomials of degrees=3, root mean squared error of the test data: 0.10835803719738028
polynomials of degrees=4, root mean squared error of the test data: 0.10666239820964532

2. Include a single plot that shows the training data as black dots and the predicted function as a blue line. (2)

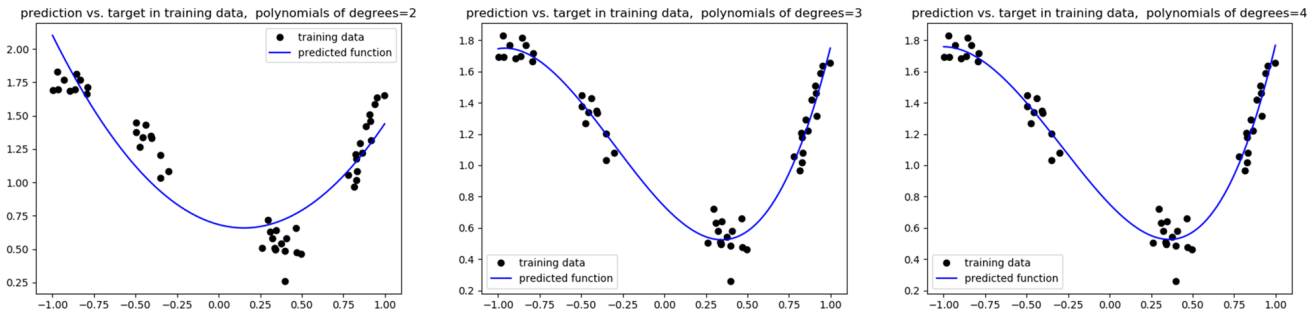

Abbildung 2: task 2

3. Why do we call this method linear regression despite using polynomials? (1)

Because of: $y_{pre} = \Phi_{hub} \cdot w$, where Φ_{hub} is the ßurrogate elementsöf polynomials.
In this formula w is also a linear weight.

```python
if __name__ == "__main__":
    # task b
    for i in range(2, 5):
        rmse_train, rmse_test = ridge_regression(data_train, data_test, n=i)
        print(f"polynomials of degrees={i-1}, root mean squared error of the training data:
            {rmse_train}")
        print(f"polynomials of degrees={i-1}, root mean squared error of the test data:
            {rmse_test}")
```

1c)

Implement 5-fold cross-validation to select the optimal degree for your polynomial regression.
• Start by splitting the provided data into 5 distinct subsets with each subset consisting of 20% of the original data.

• Use subsets 1 - 4 to train your model with polynomial features of degrees 2, 3 and 4.

• Compute the train RMSEs using your trained models and subsets 1 - 4.

• Compute the validation RMSEs using your trained models and subset 5.

• Compute the test RMSEs using your trained models and the test data.

• Repeat the previous steps, cycling through the subsets until every subset has been used for validation. Provide the following results and answers:

1. For each polynomial degree, report the average train, validation and test RMSEs among all folds. (2)

polynomials of degrees=2, root mean squared error of training: 0.20943990135161356
polynomials of degrees=3, root mean squared error of training: 0.08620813857069495
polynomials of degrees=4, root mean squared error of training: 0.08547251620354362

polynomials of degrees=2, root mean squared error of validation: 0.2248850559783977
polynomials of degrees=3, root mean squared error of validation: 0.09271100111785205
polynomials of degrees=4, root mean squared error of validation: 0.09841566883354051

polynomials of degrees=2, root mean squared error of test: 0.2183509401119271
polynomials of degrees=3, root mean squared error of test: 0.10927671570049971
polynomials of degrees=4, root mean squared error of test: 0.10867173876433611

2. Explain: Do the resulting numbers meet your expectations? Why (not)? (2)

More polynomials of degrees → more precise prediction
Reason:
As the polynomial index rises, the mapping relationship of regression will become more and more complicated

3. Which polynomial degree should be chosen for the given data? Why? (1)

Higher order polynomial could have more complex mapping, which can express more details of regression curve. But it could also lead to overfitting.

polynomials of degrees	Mean of RMSE in Test	Std of RMSE in Test
2	0.2184	0.008623
3	0.1093	0.001533
4	0.1087	0.002783

Chose polynomials of degrees 3
Though 4-order polynomials has less Mean of RMSE in cross validation than 3 order, but it shows more Std of RMSE.

```python
# task c
def fold_cross_validation(data_train, data_test, n=1, fold=5):
    """
    5 fold cross validation
    :param data_train: [array], N*2 train data
    :param data_test: [array], N*2 test data
    :param n: [int], polynomials of degrees
    :param fold: [int], fold number
    :return:
    """
    # assign fold length
    len_set = int(len(data_train)/fold)

    rmse_train_list = []
    rmse_val_list = []
    rmse_test_list = []

    # cross validation
    for i in range(1, fold+1):
        mask = np.zeros(data_train.shape)
        mask[(i-1)*len_set: i*len_set, :] = 1

        data_cv_test = data_train[mask.astype("bool")].reshape(-1, 2)
        data_cv_test = data_cv_test[np.all(data_cv_test != 0, axis=1)]

        data_cv_train = data_train[~mask.astype("bool")].reshape(-1, 2)
        data_cv_train = data_cv_train[np.all(data_cv_train != 0, axis=1)]

        rmse_train, rmse_val = ridge_regression(data_cv_train, data_cv_test, n=n, plot=False)
        _, rmse_test = ridge_regression(data_cv_train, data_test, n=n, plot=False)

        rmse_train_list.append(rmse_train)
        rmse_val_list.append(rmse_val)
        rmse_test_list.append(rmse_test)

    return np.array(rmse_train_list), np.array(rmse_val_list), np.array(rmse_test_list)

# task c
result = []
for i in range(2, 5):
    rmse_train_list, rmse_val_list, rmse_test_list = fold_cross_validation(data_train,
        data_test, n=i)
    print(f"polynomials of degrees={i}, root mean of training rmse:
        {np.mean(rmse_train_list)}")
    print(f"polynomials of degrees={i}, root mean of validation rmse:
        {np.mean(rmse_val_list)}")
    print(f"polynomials of degrees={i}, root mean of test rmse: {np.mean(rmse_test_list)}")
```

1d)

Implement Bayesian linear ridge regression, assuming that w follows a multivariate Gaussian distribution, such that

$$\mathbf{w} \sim \mathcal{N}\left(\boldsymbol{\mu}_0, \boldsymbol{\Lambda}_0^{-1}\right)$$

where ridge regression dictates $\mu_0 = 0$ and $\mathbf{\Lambda}_0 = \lambda\mathbf{I}$
Here, μ_0 is the prior weight mean and Λ_0 is the prior weight precision matrix, i.e. inverse of covariance matrix. The corresponding posterior parameters can be denoted as μ_n and Λ_n.
Assume $\sigma = 0.1$, use $\lambda = 0.01$ and include an additional input dimension to represent a bias term. Use all of the provided training data for a single Bayesian update.

1. State the posterior distribution of the model parameters $p(\mathbf{w} \mid \mathbf{X}, \mathbf{y})$ (no derivation required). (1)

$$\begin{aligned} p(\mathbf{w} \mid \mathbf{X}, \mathbf{y}, \alpha, \beta) &\propto p(\mathbf{y} \mid \mathbf{X}, \mathbf{w}, \beta) p(\mathbf{w} \mid \alpha) \\ &\propto p(\mathbf{y} \mid \mathbf{X}, \mathbf{w}, \beta) \mathcal{N}\left(\mathbf{w} \mid \mathbf{0}, \alpha^{-1}\mathbf{l}\right) \end{aligned}$$

where $p(\mathbf{w} \mid \mathbf{X}, \mathbf{y}, \alpha, \beta)$ is the posterior $p(\mathbf{y} \mid \mathbf{X}, \mathbf{w}, \beta)$ is the Likelihood of targets under the data and parameters $p(\mathbf{w} \mid \alpha)$ is the prior

With multivariate Gaussian distribution:

$$p(\mathbf{w}|\mathbf{X}, \mathbf{y}) = \frac{\exp\left(-\frac{1}{2}(\mathbf{x} - \boldsymbol{\mu_n})^{\mathrm{T}} \boldsymbol{\Lambda_n} (\mathbf{x} - \boldsymbol{\mu})\right)}{\sqrt{(2\pi)^k |\boldsymbol{\Lambda_n}|^{-1}}}$$

2. State the predictive distribution p($\mathbf{y}_* \mid \mathbf{x}_*, \mathbf{X}, \mathbf{y}$) (no derivation required). (1)

$$p\left(y_* \mid \mathbf{x}_*, \mathbf{X}, \mathbf{y}\right) = \int \underbrace{p\left(y_* \mid \mathbf{x}_*, \theta\right)}_{\text{likelihood}} \underbrace{p(\theta \mid \mathbf{X}, \mathbf{y})}_{\text{parameter posterior}} \, \mathrm{d}\theta$$

the posterior predictive distribution of y_* given $\mid \mathbf{x}_*$, $\mathbf{X}$, and $\mathbf{y}$ is calculated by marginalizing the distribution of y_* given θ over the posterior distribution of θ given $\mathbf{X}$ and $\mathbf{y}$ (which means integrate out all possible parameters θ)

The predictive distribution $p(\mathbf{y}_* \mid \mathbf{x}_*, \mathbf{X}, \mathbf{y}) = \mathcal{N}(\mathbf{y}_* | \mu(\mathbf{x}_*), \sigma^2(\mathbf{x}_*))$, thus

$$p\left(y_* \mid \mathbf{x}_*, \mathbf{X}, \mathbf{y}\right) = \frac{1}{\sigma(\mathbf{x}_*)\sqrt{2\pi}} \exp\left(-\frac{1}{2}\left(\frac{\mathbf{y}_* - \mu(\mathbf{x}_*)}{\sigma\left(\mathbf{x}_*\right)}\right)^2\right)$$

3. Report the RMSE of the train and test data under your Bayesian model (use the predictive mean). (1)

RMSE of training data: 0.41217792680573645
RMSE of test data: 0.38433605616561967

4. Report the average log-likelihood of the train and test data under your Bayesian model. (1)

average log-likelihood of training data: -1.5150672805423742
average log-likelihood of test data: -1.3940163553368101

5. Include a single plot that shows the training data as black dots, the mean of the predictive distribution as blue line and 1, 2 and 3 standard deviations of the predictive distribution in shades of blue (you can use matplotlib's fill_between function for that). (2)

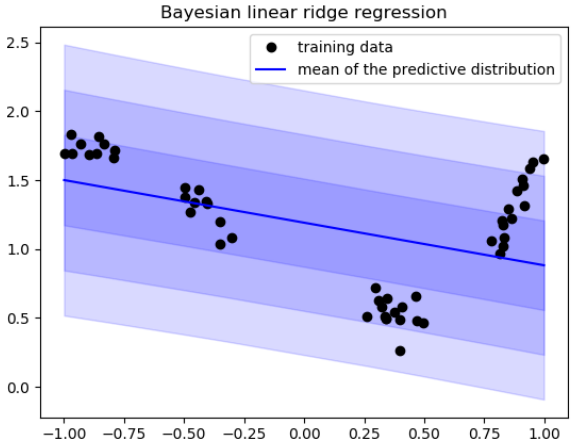

Abbildung 3: task 5

6. Explain the differences between linear regression and Bayesian linear regression. (1)

Bayesian regression is an extension of linear regression.
It predicts the variance of the result based on the Bayesian formula on the basis of linear regression. In contrast, the prediction result of linear regression is equivalent to the mean result of Bayesian regression.

1e)

Implement Bayesian linear ridge regression using squared exponential (SE) features. In other words, replace your observed data matrix $X \in \mathbb{R}^{n \times 1}$, where:

$$\Phi_{ij} = \exp\left(-\frac{1}{2}\beta\left(X_i - \alpha_j\right)^2\right).$$

Set $k = 20$, $\alpha_j = j * 0.1 - 1$ and

$\beta = 10$. Use the ridge coefficient $\lambda = 0.01$ and assume known Gaussian noise with $\sigma = 0.1$. Include an additional input dimension to represent a bias term.
1. Report the RMSE of the train and test data under your Bayesian model with SE features. (1)

RMSE of training data: 0.08241342497750634
RMSE of test data: 0.11618310002287156

2. Report the average log-likelihood of the train and test data under your Bayesian model with SE features. (1)

average log-likelihood of training data: -0.10392644293632658
average log-likelihood of test data: -0.22894630923741704

3. Include a single plot that shows the training data as black dots, the mean of the predictive distribution as blue line and 1, 2 and 3 standard deviations of the predictive distribution in shades of blue (you can use matplotlib's fill_between function for that). (2)

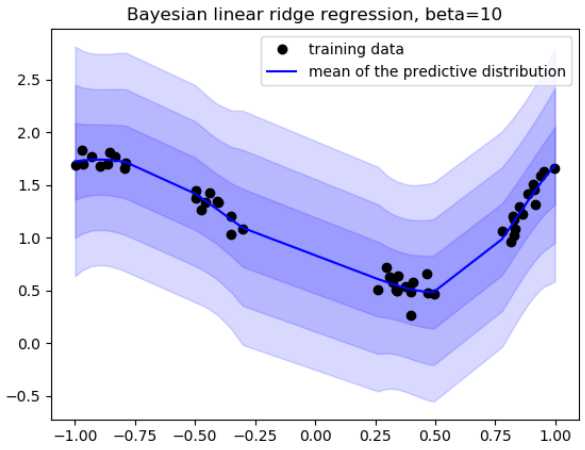

Abbildung 4: task 3

4. How can SE features be interpreted from a statisticians point of view? What are α and β in that context? (2)

SE features is a Radial Basis Function kernel (it can be interpreted as Gaussian Probability density distribution from statisticians view)
Here α means the average distance of function away from its mean;
β is a length of the 'wiggles' in function (just a scale factor).

```python
# task d, e, and f

1f)

In this bonus assignment, you will perform a grid search using $\beta \in \{1, 10, 100\}$ to select a 'better' β for your squared exponential features from the previous subtask. Keep using the same settings as in the previous subtask, except β. Grid search is a simple method to select hyperparameters, such asβ. First, a list of possible values, or a grid, in case of multiple hyperparameters, is created to define a discrete search space. For every value in this search space, a model is trained and evaluated using a score or loss function. Finally, the hyperparameters that yield the highest score or smallest loss are selected. Here, the log-marginal likelihood will be used as a score function.

The log-marginal likelihood of our Bayesian linear model can be expressed as (see Bishop Ch. 3.5)

$$\begin{aligned}\log p(\mathbf{y} \mid \mathbf{X}) &= \log \int p(\mathbf{y} \mid \mathbf{X}, \mathbf{w}) p(\mathbf{w}) \mathrm{d}\mathbf{w}, \\ &= \frac{k+1}{2} \log \lambda - \frac{n}{2} \log \sigma^2 - \frac{1}{2} \frac{\|\mathbf{y} - \Phi\mu\|_2^2}{\sigma^2} + \frac{\lambda}{2} \mu^\top \mu - \frac{1}{2} \log |\mathbf{\Lambda}| - \frac{n}{2} \log 2\pi\end{aligned}$$

where

$$\begin{aligned}\boldsymbol{\mu} &= \sigma^{-2} \mathbf{\Lambda}^{-1} \mathbf{\Phi}^\top \mathbf{y} \\ \mathbf{\Lambda} &= \sigma^{-2} \mathbf{\Phi}^\top \mathbf{\Phi} + \lambda \mathbf{I}\end{aligned}$$

Here, k is the dimensionality of the feature space, the $+1$ comes from the extra bias term. Using the marginal likelihood to select hyperparameters is typically referred to as empirical Bayes, type-II maximum likelihood or evidence approximation. Applying the logarithm (analytically) ensures numerical stability.

1. What is the difference between the marginal likelihood $p(y|X)$ and the likelihood $p(y|X, w)$? (1)

The marginal likelihood, also known as the evidence, or model evidence, is the denominator of the Bayes equation. Its only role is to guarantee that the posterior is a valid probability by making its area sum to 1.

2. For each β, report RMSE and average log-likelihood of the train and test data and the log-marginal likelihood. (3)

SE	1	10	100
RMSE of training data	0.1297	0.08241	0.07776
average log-likelihood of training data	−0.2917	−0.1039	−0.0856
RMSE of test data	0.1569	0.1162	0.1627
average log-likelihood of test data	−0.3976	−0.2289	−0.3902
log-marginal likelihood of training data	−22.3919	1.1271	3.3718
log-marginal likelihood of test data	−103.3937	−49.3719	−112.0934

3. For each beta, include a single plot that shows the training data as black dots, the mean of the predictive distribution as blue line and 1, 2 and 3 standard deviations of the predictive distribution in shades of blue (you can use matplotlib's fill_between function for that). (2)

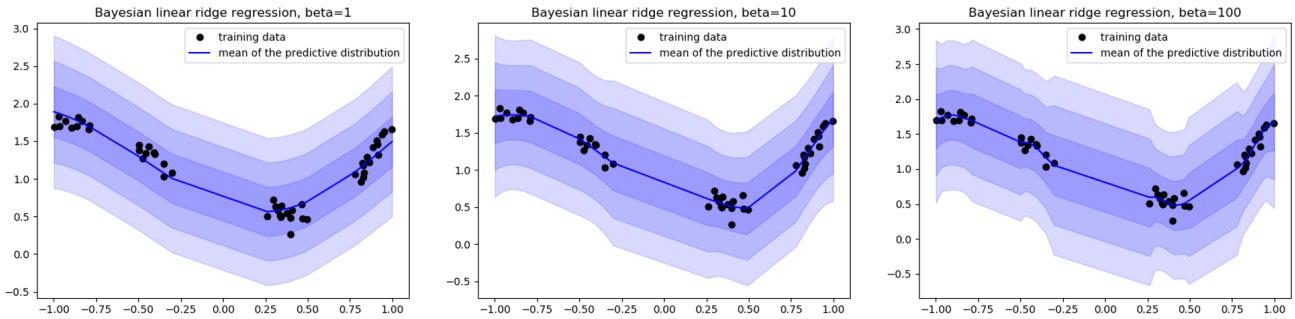

Abbildung 5: taks 3

4. According to the grid search, which value for $\beta$is the best? Why? (2)

according to RMSE in Test, best beta is 100
according to log-likelihood in Test, best beta is 10
according to log-marginal likelihood in Test, best beta is 10
Although beta = 100 performs best in RMSE, its variance is significantly larger. Based on the results of log-likelihood and log-marginal likelihood, the best beta should be 10

5. Compare the log-marginal likelihood values to the average train and test log-likelihood values. What do you observe? Is the log-marginal likelihood a 'good' score function compared to the train log-likelihood? (2)
answer:

Log-marginal likelihood includes consideration of the weight matrix mue and ridge coefficient.
In terms of loss function (ie, score function), the occurrence of overfitting can be reduced to a certain extent.

```
# task f

```

Aufgabe 2: Linear Classification

In this exercise, you will use the dataset ldaData.txt, , containing 137 feature points $\vec{x}$. The first 50 points belong to class C_1, the second 43 to class C_2, the last 44 to class C_3.

2g) 2a

Explain the difference between discriminative and generative models and give an example for each case. Which model category is generally easier to learn and why?

Answer:

In General, A Discriminative model models the decision boundary between the classes. A Generative Model explicitly models the actual distribution of each class.

A Generative Model learns the joint probability distribution $p(x, y)$. It predicts the conditional probability with the help of Bayes Theorem. A Discriminative model learns the conditional probability distribution $p(y|x)$. Both of these models were generally used in supervised learning problems.

In general generative models are easier to learn than discriminative models. Because in practice, it is usually hard to compte the postrior for discriminative models.

2h) 2b

Use Linear Discriminant Analysis to classify the points in the dataset. Attach two plots with the data points using a different color for each class: one plot with the original dataset, one with the samples classified according to your LDA classifier. Attach a snippet of your code and discuss the results. How many samples are misclassified? (You are allowed to use built-in functions for computing the mean and the covariance.)

answer:

```
# -*- coding: utf-8 -*-

import numpy as np
import matplotlib.pyplot as plt

def load_data(filename):
   data = np.loadtxt(f"D:\\Test\\dataSets\\{filename}.txt")
   C_1 = np.mat(data[:50, :]).T

   i = i + 1
plt.show()
```

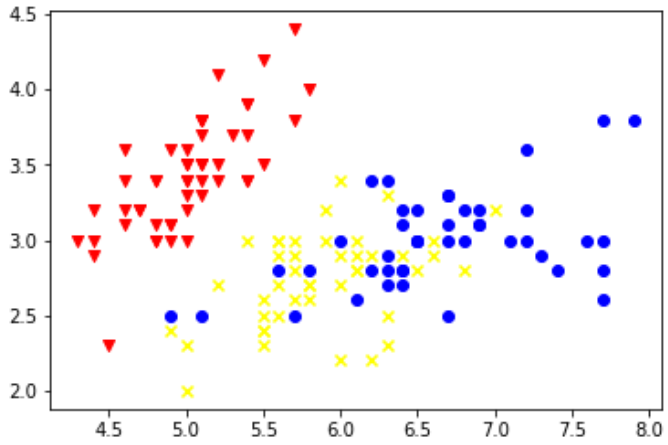

Abbildung 6: Aufgabe2b_original_classes

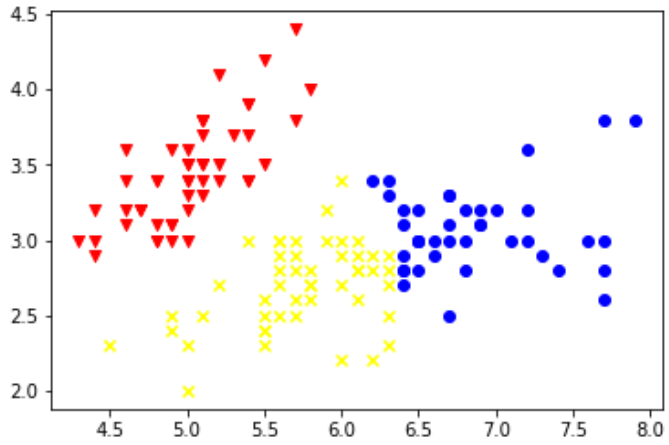

Abbildung 7: Aufgabe2b_classes_with_LDA

Aufgabe 3: Principal Component Analysis

In this exercise, you will use the dataset iris.txt. It contains data from three kind of Iris flowers ('Setosa', 'Versicolour' and 'Virginica') with 4 attributes: sepal length, sepal width, petal length, and petal width. Each row contains a sample while the last attribute is the label (0 means that the sample comes from a 'Setosa' plant, 1 from a 'Versicolour' and 2 from 'Virginica'). (You are allowed to use built-in functions for computing the mean, the covariance, eigenvalues, eigenvectors and singular value decomposition.)

3i) 3a

Normalizing the data is a common practice in machine learning. Normalize the provided dataset such that it has zero mean and unit variance per dimension. Why is normalizing important? Attach a snippet of your code.

answer:

Normalization is important in PCA since it is a variance maximizing exercise. It projects the original data onto directions which maximize the variance.
And it will give more emphasis to those variables having higher variances than to those variables with very low variances while identifying the right principle component.

```
def normalization(dataset):
   x , y = np.shape(dataset)
   for i in range( y - 1):
      dataset[: , i] = dataset[: , i] - np.mean(dataset[: , i])
      dataset[: , i] = dataset[: ,i] * np.sqrt(x / float(np.dot(np.mat(dataset[: , i]),
          np.mat(dataset[: , i]).T)))
      return x, y, dataset
```

3j) 3b

Apply PCA on your normalized dataset and generate a plot showing the proportion (percentage) of the cumulative variance explained. How many components do you need in order to explain at least 95% of the dataset variance? Attach a snippet of your code.

answer:

```
# -*- coding: utf-8 -*-

import numpy as np
import matplotlib.pyplot as plt

def load_data(filename):
   data = np.loadtxt(f"D:\\Test\\dataSets\\{filename}.txt" , delimiter = ',')
   return data

def normalization(dataset):
   x , y = np.shape(dataset)
   for i in range( y - 1):
      dataset[: , i] = dataset[: , i] - np.mean(dataset[: , i])
      dataset[: , i] = dataset[: ,i] * np.sqrt(x / float(np.dot(np.mat(dataset[: , i]),
          np.mat(dataset[: , i]).T)))
      return x, y, dataset

if __name__ == "__main__":
   data_raw = load_data('iris')
   N, M, data_norm = normalization(data_raw)

   data_cal = np.mat(data_norm[: , 0 : 4]).T
   cov_data = np.cov(data_cal)
   lambda_data , W = np.linalg.eig(cov_data)

   #3b
   lambda_norm = lambda_data / np.sum(lambda_data)
   a = np.linspace(1, M-1, M-1)
   b = np.zeros(M-1)
   for i in range(M-1):
      b[i] = np.sum(lambda_norm[: i+1])
   plt.plot(a, b)
   plt.show()
```

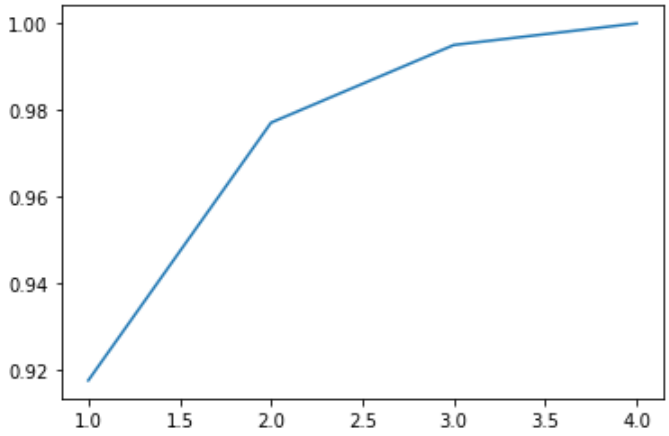

Abbildung 8: Aufgabe3b

the two first varicance are needed, to explain at least 95% of the dataset variance, as it is seen in the picture.

3k) 3c

Using as many components as needed to explain 95% of the dataset variance, generate a scatter plot of the lowerdimensional projection of the data. Use different colors or symbols for data points from different classes. What do you observe? Attach a snippet of your code.

answer:

```
# -*- coding: utf-8 -*-

import numpy as np
import matplotlib.pyplot as plt

def load_data(filename):
   data = np.loadtxt(f"D:\\Test\\dataSets\\{filename}.txt" , delimiter = ',')
   return data

def normalization(dataset):
   x , y = np.shape(dataset)
   for i in range( y - 1):
      dataset[: , i] = dataset[: , i] - np.mean(dataset[: , i])
      dataset[: , i] = dataset[: ,i] * np.sqrt(x / float(np.dot(np.mat(dataset[: , i]),
          np.mat(dataset[: , i]).T)))
      return x, y, dataset

if __name__ == "__main__":
   data_raw = load_data('iris')
   N, M, data_norm = normalization(data_raw)

   data_cal = np.mat(data_norm[: , 0 : 4]).T
   cov_data = np.cov(data_cal)
   lambda_data , W = np.linalg.eig(cov_data)

   #3c
   B = np.mat(W[: , 0: 2])
   class_2d = np.dot(B.T, (data_cal - np.mean(data_cal, 1)))
   for i in range(N):
      if data_norm[i, 4] == 0:
         plt.scatter (class_2d[0 , i], class_2d[1 , i], marker = 'v', color = 'red')
      elif data_norm[i, 4] == 1:
         plt.scatter (class_2d[0 , i], class_2d[1 , i], marker = 'x', color = 'yellow')
      else:
         plt.scatter (class_2d[0 , i], class_2d[1 , i], marker = 'o', color = 'blue')
   plt.show()
```

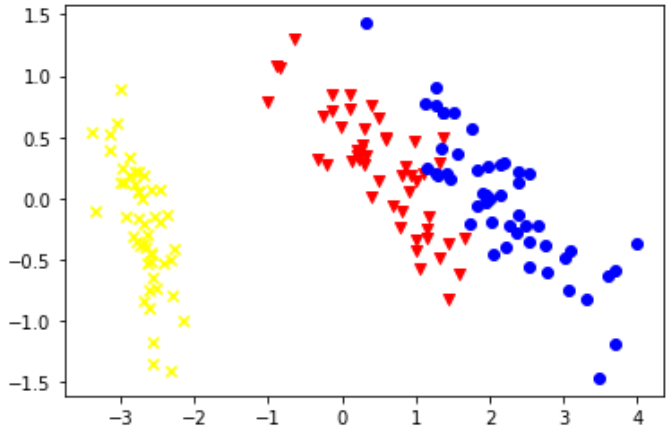

Abbildung 9: Aufgabe3c

3l) 3d

Reconstruct the original dataset by using different number of principal components. Using the normalized root mean square error (NRMSE) as a metric, fill the table below (error per input versus the amount of principal components used).

answer:

N. of components	x_1	x_2	x_3	x_4
1				
2				
3				
4				

Attach a snippet of your code. (Remember that in the first step you normalized the data.)

answer:

```
# -*- coding: utf-8 -*-

import numpy as np
import matplotlib.pyplot as plt

def load_data(filename):
   data = np.loadtxt(f"D:\\Test\\dataSets\\{filename}.txt" , delimiter = ',')
   return data

if __name__ == "__main__":
   data_raw = load_data('iris')
   #3d
   data_cal_raw = np.mat(data_raw[: , 0 : 4]).T
   error = np.mat(np.zeros((4,4)))
   cov_data_raw = np.cov(data_cal_raw)
   lambda_data_raw , W_raw = np.linalg.eig(cov_data_raw)
   for i in range(M - 1):
      B_raw = np.mat(W_raw[:, 0: i+1])
      class_2d_raw = np.dot(B_raw.T, (data_cal_raw - np.mean(data_cal_raw, 1)))
      datau_cal = np.mean(data_cal_raw, 1) + np.dot(B_raw ,class_2d_raw)
      error[i, :] = np.sqrt(np.sum(np.power((data_cal_raw - datau_cal), 2), 1) / N).T
   print(error)
```

As a result the table will be filled:

N. of components	x_1	x_2	x_3	x_4
1	0.4137	0.4010	0.1615	0.2058
2	0.1485	0.2131	0.0813	0.1929
3	0.0389	0.0496	0.0753	0.1209
4	0	0	0	0

3m) 3e

In machine learning, it is often desirable to 'whiten' the data before applying a model or an algorithm. In this context, 'whitening' the data refers to a transformation that warps the data into a spherical shape, such that the data dimensions become uncorrelated and the individual means and variances are 0 and 1, respectively. In particular, PCA can be used to compute such a transformation.
Recommended reading: ufldl.stanford.edu/tutorial/unsupervised/PCAWhitening

1. Explain the difference between PCA and ZCA whitening. (1)

For PCA whiting , the Covariance is exact 1, and for ZCA whiting , the Covariance is same but not strict 1. And PCA wihting can be done to reduce the demension, while ZCA is more used to uncorrelate.

2. State the equation(s) to compute the ZCA whitening parameters, given the data. (1)

$$X_{\text{ZCAwhiting}} = U X_{\text{PCAWhite},i}$$

3. State the equation(s) to whiten a (new) data example x, given the ZCA parameters. (1)

$$\begin{aligned}
\Sigma &= \frac{1}{m} X X^T \\
\frac{1}{m} X X^T &= U A U^T \\
X_{rot} &= U^T X \\
X_{\text{PCAwhite},i} &= \frac{X_{\text{rot},i}}{\sqrt{\lambda_i + e}}, e = 1.0e^{-5} \\
X_{\text{ZCAwhiting}} &= U X_{\text{PCAWhite},i}
\end{aligned}$$

4. Compute and report the ZCA whitening parameters for the unnormalized IRIS data (including numerical values!). For numerical stability, use $\epsilon = 1e - 5$ (2)

3n) 3f

Throughout this class we have seen that PCA is an easy and efficient way to reduce the dimensionality of some data. However, it is able to detect only linear dependences among data points. A more sophisticated extension to PCA, Kernel PCA, is able to overcome this limitation. This question asks you to deepen this topic by conducting some research by yourself: explain what Kernel PCA is, how it works and what are its main limitations. Be as concise (but clear) as possible.

answer:

Kernel PCA: an extension of principal component analysis (PCA) using techniques of kernel methods. Using a kernel, the originally linear operations of PCA are performed in a reproducing kernel Hilbert space.
Process: Solve the following eigenvalue problem:

$$Ku_i = \lambda_i u_i, \lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_N$$

The projection of the test sample $\Phi(X_j)$ on the i_th eigenvector can be computed by

$$Ku_i = \lambda_i u_i, \lambda_1 \geq \lambda_2 \geq \ldots \geq \lambda_N v_i^T \Phi(x_j) = \frac{1}{\sqrt{\lambda_j}} u_i^T \begin{bmatrix} K(x_1, x_j) \\ \vdots \\ K(x_N, x_j) \end{bmatrix}$$

limitations:
a) PCA assumes a linear transformation: $\rightarrow$ With centering of data, one can only do a rotation in space.
b) It fails at finding directions that require a non-linear transformation.
